ABSTRACT. A novel Finite Element Method (FEM) for the computational simulation in particle reinforced composite materials with many inclusions is presented. It is based on a specially designed mesh consisting of triangles and channel-like connections between inclusions which form a network structure. The total number of elements and, hence, the number of degrees of freedom are proportional to the number of inclusions. The error of the method is independent of the possibly tiny distances of neighbouring inclusions.

We present algorithmic details for the generation of the problem adapted mesh and derive an efficient residual a posteriori error estimator which enables to compute reliable upper and lower error bounds. Several numerical examples illustrate the performance of the method and the error estimator. In particular, it is demonstrated that the (common) assumption of a lattice structure of inclusions can easily lead to incorrect predictions about material properties.

1. INTRODUCTION

Particle reinforced composite materials are engineered materials which consist of different constituents with the aim to obtain physical properties better than what the used materials have on their own, i.e., a beneficial combination of the employed materials. The specific properties of the composite material strongly depend on macroscopic parameters such as the volume fraction and microscopic geometric features of the constituents. They thus represent a typical multiscale problem for analysis and computation.

For this paper, the effective conductivity of two-phase materials consisting of many randomly dispersed highly conducting filler particles (inclusions) and a poorly conducting binder material (matrix) shall be investigated. Typically, the matrix material exhibits favourable mechanical features while the inclusions determine the “functional” properties. For our purposes, the contrast of conductivity between inclusions and matrix is high, i.e., in our model we assume the inclusions to be ideal conductors.

Although there are many results about how to analyse problems of this kind if the microstructure of the material is structured or periodic (homogenization theory), see e.g. [Kel63, KS64] and [ABP78, UKO94, CD00, BP89], the mathematical treatment is much less clear for unstructured distributions of particles. In particular, phenomena specific to the lack of a regular structure play a crucial role since they can be responsible for drastic changes in material properties when the composition of the material is changed only slightly. One such well-known phenomenon is the percolation effect [Kes92, Gri92] which can be observed for densely packed filler particles which occasionally form connected paths and thus strongly amplify the conducting property, see [BK01, BN02].

Since the prediction of the behaviour of a composite material on the one hand is crucial during the engineering process but on the other hand often is intractable analytically, numerical simulations can provide valuable insights with regard to effective material properties. Additionally, they can provide convenient means to test many different setups with the aim to obtain a specific material behaviour.

For the Poisson-type model problem with discontinuous diffusion coefficient (introduced in the next section), a classical numerical method is the finite element method (FEM) which is based on a partition of the domain. In order to achieve accurate numerical results, the employed mesh would have to resolve the microscopic geometric structure of the problem. Since inclusions are irregularly distributed in the matrix and their volume fraction is large, they often are close to
touching one another. The material responses depend crucially on these tiny distances. Thus, they have to be resolved accurately by the underlying mesh for the simulation to be reliable. The generation of a mesh appropriate for numerical simulation for such a domain is difficult and requires the use of many elements which consequently leads to a (possibly prohibitively) high complexity in the solution process, see Figure 1 for a simple setting which already requires a very large number of mesh elements. As can be observed, the diameter of the smallest FEM elements in Figure 1 scales at most like the minimal distance between inclusions.

Moreover, since the distribution of particles may be based on a random distribution, in order to determine the characteristic properties of a certain setup, a large set of realisations of the geometry has to be evaluated for the calculation of expected properties. Thus, the complexity for the required mesh generation and the resulting (linear) algebraic system to be solved are crucial and limiting factors.

The method promoted in this article is capable to yield accurate and reliable results for the described problem with low computational complexity. This is achieved by a specific partition of the domain which is inspired by discrete network methods [BP98, BK01, BN02] (we refer to the recent textbook [BKN13] for an overview on this methodology) and resolves the inclusions exactly while still remaining close to the classical FEM, both in implementation and the analytical results. Figure 1 also shows the adapted mesh which is of nearly optimal complexity, i.e., the number of elements is proportional to the number of inclusions. In particular, the complexity does not scale with the infinitesimal distance between inclusions. Still, the discrete model accounts for the complexity of the microstructure and provides a good overall macroscopic response, see Sections 2 and 3.

1.1. Model Problem. We consider the Poisson model problem on some perforated domain \( \Omega \subset \mathbb{R}^2 \) which results from some simply connected polygonal domain \( \Omega^* \subset \mathbb{R}^2 \) by removing a union of circular inclusions \( \Omega_{\text{inc}} \).

The set of closed, pairwise disjoint discs with positive radii is denoted \( B_{\text{inc}} \), i.e., for any \( B_1, B_2 \in B_{\text{inc}} \) with \( B_1 \neq B_2 \),

\[
\tag{1.1}
B_1, B_2 \subset \Omega \quad \text{and} \quad \text{dist}(B_1, B_2) > 0.
\]

The two phases of the material are represented by the set of the inclusions \( \Omega_{\text{inc}} \) and the so-called matrix \( \Omega \),

\[
\tag{1.2}
\Omega_{\text{inc}} := \bigcup_{B \in B_{\text{inc}}} \text{int}(B) \quad \text{and} \quad \Omega := \Omega^* \setminus \overline{\Omega_{\text{inc}}}
\]

We assume the number of inclusions \( N_{\text{inc}} := \# B_{\text{inc}} \) to be very large such that \( \Omega_{\text{inc}} \) occupies a significant amount of the volume of \( \Omega^* \).

The problem then reads

\[
\tag{1.3a}
- \text{div } \nabla u = f \quad \text{in } \Omega,
\]

\[
\tag{1.3b}
u = u_D \quad \text{on } \Gamma_D,
\]

\[
\tag{1.3c}
\partial_n u \cdot n = 0 \quad \text{on } \Gamma_N,
\]

\[
\tag{1.3d}
\forall B \in B_{\text{inc}} : \quad u_{|_{\partial B}} \equiv \text{const} \quad \text{and} \quad \int_{\partial B} \frac{\partial u}{\partial n_B} \, ds = 0,
\]
with $f \in L^2(\Omega)$, also see [BK01]. The outer normal to some Lipschitz domain $\omega$ is denoted by $n_\omega$. We just write $n$ if $\omega = \Omega$. Sufficiently smooth Dirichlet boundary data $u_D$ is imposed on the closed set $\Gamma_D \subset \partial \Omega^*$ with positive surface measure while homogeneous Neumann data is prescribed on $\Gamma_N := \partial \Omega^* \setminus \Gamma_D$. To reduce technical overhead, we will assume later that $u_D$ is included in our discrete space, i.e., $u_D$ is piecewise affine with respect to some subdivision of $\Gamma_D$. Otherwise, errors due to the approximation of the boundary values have to be considered.

Define the vector space

$$V := \left\{ v \in H^1(\Omega) \mid v|_{\Gamma_D} = 0 \text{ and } \forall B \in \mathcal{B}_{inc} \exists c_B \in \mathbb{R} : v|_{\partial B} = c_B \right\}.$$
Note that any \( v \in V \) has a unique extension \( v^* \in H^1(\Omega^*) \) with \( v^*|_\Omega = v \) and \( \nabla v^*|_{\Omega^* \setminus \Omega} = 0 \) because the trace of \( u \) on the boundary of an inclusion is constant. The variational formulation of (1.3) reads: Find \( u \in u_D + V \) such that, for all \( v \in V \),

\[
(1.4) \quad a(u,v) := \int_\Omega \nabla u \cdot \nabla v \, dx = \int_\Omega f v \, dx =: F(v).
\]

Using the Friedrichs inequality, the coercivity of the continuous bilinear form \( a \) can readily be seen by

\[
(1.5) \quad a(v,v) = \int_\Omega |\nabla v|^2 \, dx = \int_\Omega |\nabla v^*|^2 \, dx \geq ||v^*||_{H^1(\Omega^*)}^2 \geq ||v||_{H^1(\Omega)}^2
\]

for \( v \in V \). This coercivity along with the symmetry and boundedness of \( a \), and the boundedness of \( F \) implies the unique solvability of Equation (1.4).

Note that the unique weak solution \( u \) of formulation (1.3) is also the unique minimiser of the quadratic energy functional

\[
(1.6) \quad E(v) := \frac{1}{2} \int_\Omega |\nabla v(x)|^2 \, dx - \int_\Omega f(x)v(x) \, dx
\]

amongst all \( v \in u_D + V \).

1.2. Outline. Section 2 presents the novel Network FEM (NFEM). Opposite to [CP11], we pursue a practical approach which includes algorithmic details regarding the actual implementation of the NFEM. These have not been described elsewhere and it is our hope that the presentation fosters the popularity of this promising numerical approach. We describe the underlying subdivision which exactly represents the geometry of the domain. The globally continuous approximation space is build as the union of local transformations of affine spaces on parametrized quadrilaterals (the “channels” between inclusions) and triangles. The crucial point is that the dimension of the resulting space is the same as the number of inclusions due to the construction of the adapted mesh. Thus, the complexity of the discretization is proportional to the complexity of the geometry representation (centers and radii of inclusions) and, hence, (quasi-)minimal. Interpolation error estimates and a priori error bounds are recalled. Section 3 is concerned with the derivation of some residual a posteriori error estimator which provides a computable error bound of the error of the discrete solution. It potentially also could steer an adaptive algorithm. We prove reliability and efficiency of the error estimator which, while being based on arguments from classical FEM, requires some new non-trivial and non-standard estimates due to the specific features of the mesh. Numerical validation of the Network FEM and the a posteriori error estimator is given in Section 4. The percolation phenomenon is shown experimentally. It can be observed when the inclusions reach a very high density such that they are in contact with neighbouring inclusions. A remarkable observation is that the common modelling assumption of a structured distribution leads to fundamentally different results than random distributions of inclusions even when the volume fraction is identical. We finish in Section 5 with some conclusions and an outlook.

1.3. Notation. We use the common notation for Sobolev spaces of functions defined on a domain \( \Omega \subset \mathbb{R}^2 \). By \( H^k(\Omega) \) the space of all functions in \( L^2(\Omega) \) which exhibit weak derivatives up to order \( k \) is defined.
In estimates, the notation $A \lesssim B$ abbreviates $A \leq CB$ with some multiplicative constant $C > 0$ which only depends on the domain $\Omega$ and the shape but not on the mesh size $h$ of finite element domains. Furthermore, $A \approx B$ abbreviates $A \leq B \leq A$.

(a) Generalized Voronoi cells for set $B$ of discs.
(b) Isoparametric quadrilaterals $Q$ (shaded in gray) connecting any two discs of $B$ which are associated to some Voronoi edge in $E^\circ$ (black curves).
(c) Triangles $T$ (shaded in gray) associated to Voronoi vertices (black dots) occupy the remaining sisting of isoparametric quadrilateral and triangular space between quadrilaterals of $Q$.
(d) Final grid $G = Q \cup T$ (shaded in gray) consisting of isoparametric quadrilateral and triangular elements.

**Figure 2.** Illustration of the grid construction in Section 2.1

2. Network FEM

In this section, we recall the problem-adapted mesh and the construction of the conforming first-order discrete approximation space $[CP11]$. The mesh has to take into account the geometrical
features of the domain, i.e., many circular inclusions, which is achieved by a combination of curvilinear quadrilaterals and triangular elements.

2.1. Grid Construction. The underlying geometry of the problem is determined by the set of (finitely many) closed discs \( \mathcal{B} \). Each \( B \in \mathcal{B} \) is defined by its center \( c_B = \text{mid}(B) \) and the radius \( r_B := \text{diam}(B)/2 \geq 0 \). Note that also discs with radius zero are admissible. The elements of \( \mathcal{B} \) are denoted as generalized vertices. They are partitioned into the set of inclusions \( \mathcal{B}_{\text{inc}} \) and discs with vanishing radius \( \mathcal{B}_{\text{mat}} \)

\[
\mathcal{B} = \mathcal{B}_{\text{inc}} \cup \mathcal{B}_{\text{mat}} \quad \text{and} \quad \mathcal{B}_{\text{inc}} \cap \mathcal{B}_{\text{mat}} = \emptyset.
\]

The set \( \mathcal{B}_{\text{mat}} \) contains points on the boundary of \( \Omega \) necessary to represent the domain adequately, e.g., the corner points of the domain and all points where the boundary condition switches from Neumann to Dirichlet. In order to control the approximation quality locally, it would be possible to add additional interior points to the set \( \mathcal{B}_{\text{mat}} \). This for instance could be done by an adaptive algorithm based on the residual error estimator described in Section 3. However, the presented theory does not cover this case although a generalisation seems straight-forward.

In the following we provide an algorithmic description for the generation of the generalized mesh of the Network FEM.

Voronoi diagram of the inclusions. Pivotal to the construction of an appropriate mesh for the complex geometry of the matrix \( \Omega = \Omega_{\text{mat}} \) is the (additively weighted) Voronoi diagram with regard to the set of discs \( \mathcal{B} \). We refer to [AK00] and references therein. We mark sets of the Voronoi construction by a subscript \( \circ \). In case of equi-sized discs, the Voronoi cells \( C \in C_\circ \) are defined by straight line segments which become curved when the disc radii differ, see Figure 2. Each Voronoi cell \( C \in C_\circ \) is defined by a set of Voronoi edges \( E \in E_\circ \) and each edge is defined by two Voronoi vertices in the set of Voronoi vertices \( \mathcal{N}_\circ(\Omega) \). For notational convenience, we define the following maps which relate these entities.

neighbours

\[
B_1, B_2 \in \mathcal{B} : \quad E_\circ(B_1, B_2) \quad \text{unique Voronoi edge associated with } B_1, B_2, \text{ i.e.,}
E_\circ(B_1, B_2) = \{ x \in \mathbb{R}^2 \mid \text{dist}(x, B_1) = \text{dist}(x, B_2) = \min_{B \in \mathcal{B}} \text{dist}(x, B) \}
\]

\[
\forall B \in \mathcal{B} : \quad E_\circ(B) \quad \text{set of Voronoi edges associated to disc } B, \text{ i.e.,}
E_\circ(B) = \{ E_\circ(B_1, B) \mid B_1 \in \mathcal{B} \text{ and } E_\circ(B_1, B) \in E_\circ \}
\]

\[
\forall E \in E_\circ : \quad \mathcal{N}_\circ(E) \quad \text{set of two vertices of edge } E
\]

\[
\forall E \in E_\circ : \quad \mathcal{B}(E) \quad \text{set of two neighboring discs, i.e., with } E = E_\circ(B_1, B_2),
\forall x \in E \text{ dist}(x, B_1) = \text{dist}(x, B_2) = \min_{B \in \mathcal{B}} \text{dist}(x, B)
\]

\[
\forall p \in \mathcal{N}_\circ : \quad \mathcal{B}(p) \quad \text{set of neighboring discs, i.e.,}
\mathcal{B}(p) = \{ B \in \mathcal{B} \mid \text{dist } p, B = \min_{B \in \mathcal{B}} \text{dist}(p, B) \}.
\]

Our construction process for the mesh generates two types of elements. First, an isoparametric quadrilateral is obtained for each Voronoi edge \( E \in E_\circ \) which results in the set of quadrilaterals \( Q \). Second, the remaining polygonal areas \( \Omega \setminus \bigcup Q \) are decomposed into the set of triangles \( \mathcal{T} \). The union then fulfils \( \bigcup \mathcal{T} \cup \bigcup Q = \Omega \) and we set \( \mathcal{G} := Q \cup \mathcal{T} \) the subdivision of \( \Omega \). The
set of edges is denoted by $E$, the restriction to interior edges is $E_{\text{int}} := \{ E \in E \mid E \cap \Omega \neq \emptyset \}$ and the restriction to boundary edges on $\Gamma$ is defined by $E(\Gamma)$.

The notation and further details are provided in the following Subsections. A similar construction in the context of the discrete network approximation method can be found in [BK01].

Algorithm 1 geometry adapted mesh construction

Require: domain $\Omega^*$, set of discs $B$ mesh $\mathcal{G} = Q \cup T$ of $\Omega = \Omega^* \setminus B$ into isoparametric quadrilaterals $Q$ and triangles $T$

$(C_o, E_o, N_o) \leftarrow$ compute Voronoi diagram for $(\Omega, B)$

$Q \leftarrow \emptyset$, $T \leftarrow \emptyset$ [initialization]

for all $E \in E_o$ do

$(B_1, B_2) \leftarrow B(E)$ neighbouring discs associated with $E$

$a, b \leftarrow$ vertices of $E$

$c_1, c_2 \leftarrow$ centers of $B_1, B_2$

$a_1, b_1 \leftarrow$ intersection of line segments $\overline{c_1a}$ and $\overline{c_1b}$ with $\partial B_1$

$a_2, b_2 \leftarrow$ intersection of line segments $\overline{c_2a}$ and $\overline{c_2b}$ with $\partial B_2$

$s_1 \leftarrow$ boundary segment of $\partial B_1$ between $a_1$ and $b_1$

$s_2 \leftarrow$ boundary segment of $\partial B_2$ between $a_2$ and $b_2$

$Q \leftarrow Q \cup$ isoparametric quadrilateral $(s_1, a_1a_2, s_2, b_2a_2)$

end for

for all $P \in N_o$ do

$\Lambda \leftarrow B(P)$ discs associated with Voronoi vertex $P$

$c_1, \ldots, c_n \leftarrow$ centers of discs $B \in \Lambda$

$A \leftarrow \emptyset$ [initialization]

for all $B \in \Lambda$ do

$c \leftarrow$ center of $B$

$A \leftarrow A \cup \{ a \}$ intersection of line segment $\overline{cP}$ with $\partial B$

end for

$T \leftarrow T \cup$ decomposition of $\text{conv}(A)$ into triangles

end for

$\mathcal{G} \leftarrow Q \cup T$

Local construction of quadrilaterals. For some Voronoi edge $E \in E_o$ with Voronoi vertices $\{p_1, p_2\} = N_o(E)$, the corresponding discs with centers $c_1, c_2 > 0$ are $\{B_1, B_2\} = B(E)$. We connect center $c_1$ with $p_1$ and $p_2$ and denote the intersections with disc $B_1$ by $a_1$ and $b_1$, respectively. The same is done with $c_2$ which results in $a_2, b_2$. The channel-like element $Q_E \in Q$ of edge $E$ is then defined by the line segments $\overline{a_1a_2} = \text{conv}\{a_1, a_2\}$, $\overline{b_1b_2} = \text{conv}\{b_1, b_2\}$ and the sections on the discs $B_1, B_2$ which lie in between $a_1, b_1$ and $a_2, b_2$, respectively.

This procedure has to be carried out for all edges $E \in E_o$ and provides the set of curvilinear quadrilaterals $Q$. Note that if either one or both of the discs deteriorate to a point, we obtain either a curvilinear triangle or a line segment. The latter case is discarded.

Remark 2.1. Note that the Voronoi dual edge might not be connected (see Figure 3). The same applies to the corresponding isoparametric quadrilaterals as can be seen in the same figure. We denote the number of connected components of $Q \in Q$ by $K(Q)$. The parametrisation from Definition 2.1 applies to every connected component of $Q$. 
Fig. 3. Generalized Voronoi and corresponding grid; Voronoi edges and corresponding isoparametric quadrilateral multiply connected.

Trigonals. The above algorithm yields the set $Q$ and the entire surface of each disc is associated with a set of quadrilaterals from the set $Q$, i.e., for any $B \in B$, $\partial B = \bigcup_{Q \in Q(B)} B \cap Q$. The remaining areas in $\Omega^*$ which are not occupied by either a disc or a quadrilateral are polygons. In fact, a polygon $P_p$ with $n$ edges is associated with each Voronoi vertex $p \in N$ where $n = \#B(p)$ and $P_p := \text{conv}\{a_1, \ldots, a_n\}$ with $a_1, \ldots, a_n$ the intersection points of the connections of the disc centers of each $B(p)$ with $p$. We decompose each such polygon into a set of triangles which results in the set $T$. The adapted mesh is then given by $G := Q \cup T$.

2.2. Mapping to quadrilateral elements. The result of the construction of the previous section is a set $G$ of elements which is a decomposition of the domain $\Omega$. It consists of a set of isoparametric quadrilaterals $Q$ and a set of triangles $T$. By $E$ we denote the set of edges of the elements of $G$.

For the transformation from a reference rectangle $E^{\text{ref}} := [\alpha, \beta] \times [0, 1]$ to curvilinear quadrilaterals (and triangles), we apply the following mapping.

Definition 2.1 (mapping onto curvilinear quadrilaterals). Consider the circular inclusions $B_1, B_2 \in B$, $B_1 \cap B_2 = \emptyset$, with radii $r_1, r_2$ and connecting quadrilateral $Q \in Q$. The coordinate system can be rotated and shifted such that, without loss of generality, the centers of the discs are given by $c_1 = (0, 0)$ and $c_2 = (0, \delta)$ and $\delta > r_1 + r_2$. With angles $-\pi/2 \leq \alpha \leq \beta \leq \pi/2$ and $Q \in Q$, define the map $J_Q : [\alpha, \beta] \times [0, 1] \to \text{int}(Q)$ by

$$J_Q(s, \lambda) := \left(1 - \lambda r_1 + \lambda r_2 \left(\frac{r_1 + H(s)}{r_2 + H(s)}\right)\right)\left[\begin{array}{c} \sin(s) \\ \cos(s) \end{array}\right] + \delta \lambda \left(1 - \frac{r_2}{r_2 + H(s)}\right)\left[\begin{array}{c} 0 \\ 1 \end{array}\right],$$

where

$$H(s) := \frac{\delta^2 - 2 \cos(s) \delta r_1 + r_1^2 - r_2^2}{(2 r_2 - 2 r_1) + 2 \delta \cos(s)}.$$

See Figure 4(left) for an illustration.

2.2.1. Local mesh size. For any triangle $T \in T$, $h_T := \text{diam}(T)$ denotes its size parameter. Analogously, for any edge $E \in E$, i.e., $h_E := \text{diam}(E)$. For $Q \in Q$, the definition of the mesh
size $h_Q$ is more involved since it is subject to the mapping $J_Q$ of Definition 2.1. We set, for $x \in Q$ and $(s, \lambda) = J_Q^{-1}(x)$,

$$h(x) := \left\| J_Q(s, 1) - J_Q(s, 0) \right\|_{\mathbb{R}^2}.$$

Note that $h$ varies within each quadrilateral. Then, the piecewise continuous global mesh size function $h$ is defined by

$$h|_G := h_G \quad \text{for } G \in \mathcal{G}.$$

Moreover, we define the vertex and edge patches

(2.2) for $B \in \mathcal{B}$ : $\omega_B := B \cup \{G \in \mathcal{G} : G \cap B \neq \emptyset\}$,

(2.3) for $E \in \mathcal{E}$ : $\omega_E := B \cup \{G \in \mathcal{G} : G \cap E \neq \emptyset\}$.

2.3. Finite Element Space. The discrete approximation space has the same dimension as the cardinality of the set of vertices $|\mathcal{B}|$ of the mesh as in standard first-order FEM as defined below. Dirichlet boundary nodes are fixed and thus do not contribute to the dimension of the linear system. Associated to every $B \in \mathcal{B}$ is some basis function $\lambda_B : \Omega^* \rightarrow [0, 1]$ determined by the conditions

a) $\lambda_B \equiv 1$ on $B$ and $\lambda_B \equiv 0$ on $\mathcal{B} \setminus B$,

b) $\forall T \in \mathcal{T}$, $\lambda_B|_T$ is affine,

c) $\forall Q \in \mathcal{Q}$, $\lambda_B|_Q \circ J_Q$ is affine with respect to the reference element $Q_{ref}$, and

d) $\lambda_B$ is continuous.

These basis functions generalise nodal basis functions on classical triangular meshes. The support of $\lambda_B$ is given by

$$\text{supp}(\lambda_B) = B \cup \omega_B$$

with the vertex patch $\omega_B$ defined in (2.2).

The transformation of affine base functions on the reference rectangle $Q_{ref}$ onto curvilinear quadrilaterals $Q \in \mathcal{Q}$ is be achieved by the mapping $J_Q$ of Definition 2.1. Figure 4 illustrates this mapping from some reference rectangle to the quadrilateral and a transformed base function associated to some node restricted to the quadrilateral.

The set of basis functions $\Lambda := \{\lambda_B : B \in \mathcal{B}\}$ forms a partition of unity in $\Omega$. The finite element space

$$S := \text{span}(\Lambda) \cap V$$

is then spanned by the nodal basis functions $\lambda_B$ of all $B \in \mathcal{B}$ which do not correspond to nodes on the Dirichlet boundary $\Gamma_D$.

The discrete problem reads: Find $u_{\text{NFEM}} \in u_D + V$ such that, for all $v \in V$,

$$a(u_{\text{NFEM}}, v) = F(v).$$

If $u$ is sufficiently smooth, the error of the discrete solution $u_{\text{NFEM}} \in u_D + V$ satisfies [CP11]

(2.4) $\|\nabla(u - u_{\text{NFEM}})\|_{L^2(\Omega)} \lesssim \|h\nabla^2 u\|_{L^2(\Omega)}$.

Moreover, the solution $u$ satisfies [Pet12]

(2.5) $\|h\nabla^2 u\|_{L^2(\Omega)} \lesssim \|f\|_{L^2(\Omega)}.$
We stress that the implicit constants in the previous two estimates do not depend on the tiny distances between neighbouring inclusions.

3. A POSTERIORI ESTIMATOR

A posteriori error control allows to assess the quality of the discrete solution and provides upper and lower bounds for the global error. Although it is well established with standard FEM, see [AO00, Ver96], an extension to NFEM is not immediate. Instead, it requires the application of some non-trivial interpolation estimates as detailed in Subsection 3.1.

This section is concerned with the derivation of some residual a posteriori error estimator $\eta$ based on a mesh $\mathcal{G}$. The aim of the estimator is to bound the error $e := u - u_{\text{NFEM}}$ in the energy norm. Two-sided bounds ensure that the estimator is sufficiently accurate.

Higher-order terms due to properties of the data enter the estimates in the form of oscillations. On some $G \in \mathcal{G}$, let $f_G := |G|^{-1} \int_G f \, dx$ be the average of $f \in L^2(\Omega)$ in $G$. The global $\mathcal{G}$-piecewise constant function $f_G$ is defined by $f_G|_G = f_G$ for $G \in \mathcal{G}$. Then, define oscillations on $\mathcal{G}$ by

$$\text{osc}(f, \mathcal{G}) := \left\| h_G (f - f_G) \right\|_{L^2(\Omega)},$$

Define the computable interior and the edge residual $r_T$ and $r_E$ by

$$r_G := f + \text{div}_G \nabla_{G} u_{\text{NFEM}} \quad \text{in} \ G \in \mathcal{G},$$

$$r_E := \begin{cases} -\nabla u_{\text{NFEM}} \cdot n_E & \text{on} \ E(\Gamma_N), \\ -[\nabla u_{\text{NFEM}} \cdot n_E]_E & \text{on all other} \ E \in \mathcal{E} \end{cases}$$

and set $\tilde{r}_G := r_G + (f_G - f)$. By the subscript in $\text{div}_G$ and $\nabla_{G}$ we denote the piecewise application of the differential operator.
The error estimator then reads
\[ \eta := \left( \sum_{G \in \mathcal{G}} \| h_G r_G \|_{L^2(G)}^2 + \sum_{E \in \mathcal{E}} h_E \| r_E \|_{L^2(E)}^2 \right)^{1/2}. \]

We call an estimator reliable if \( \| \nabla e \|_{L^2(\Omega)} \lesssim \eta \) and efficient if \( \eta \lesssim \| \nabla e \|_{L^2(\Omega)} \).

The main result is the following theorem.

**Theorem 3.1.** Given the discrete solution \( u_{\text{NFEM}} \in u_D + V \), the a posteriori error estimator \( \eta \) is reliable and efficient, i.e., with oscillations (3.1), it holds
\[
\| \nabla (u - u_{\text{NFEM}}) \|_{L^2(\Omega)} \lesssim \eta \quad \text{and} \quad \eta \lesssim \| \nabla (u - u_{\text{NFEM}}) \|_{L^2(\Omega)} + \text{osc}(f, \mathcal{G}).
\]

**Remark 3.1.** The first estimate is independent of all mesh related parameters except the angles of the elements. The implicit constants in the second estimate depends on the geometry in the following sense. The constant is proportional to the maximal ratio of the distance of neighbouring inclusions and their radii, i.e., the constant reflects the diameter of areas in the material with no inclusion relative to the radii of the inclusions. Since we are mainly interested in numerical experiments where the reliability of the estimator is crucial, we do not further investigate this issue.

The proof of the theorem is provided in Subsections 3.2 and 3.3. The specific properties of the specially designed mesh and the respective discrete space impose complications in the derivation which are not encountered in standard FEM. This is reflected by the crucial fact that some norms are weighted by the mesh size \( h_T \) since it is non-constant on the elements \( Q \subseteq \mathcal{G} \).

In the following, we prove the reliability of the a posteriori estimator independent of the critical geometric parameters of \( \Omega \).

### 3.1. Interpolation.

We will use the interpolation operator \( I : V \to S \) defined for \( v \in V \) by
\[
(3.2) \quad Iv := \sum_{B \in B_{\text{nc}}} v|_B \lambda_B + \sum_{B \in B_{\text{mat}} \cap \Gamma_N} \left( |\omega_B| \int_{\omega_B} v dx \right) \lambda_B.
\]

The operator \( I \) is well-defined for any function in \( v \in V \), because \( v|_B \) is not a point evaluation but the volume average of \( v \) on the inclusion \( B \in B_{\text{nc}} \). For vertices on the Neumann boundary, we perform standard Clément-type averaging. The resulting interpolation is locally stable in the following sense.

**Lemma 3.2** (stability of the interpolation). For any \( v \in V \) it holds
\[
\| \nabla Iv \|_{L^2(G)} \lesssim \| \nabla v \|_{L^2(\omega_G)} \quad \text{on any } G \in \mathcal{G},
\]
where \( \omega_G := \cup \{ K \in \mathcal{G} \mid \bar{K} \cap \bar{G} \neq \emptyset \} \).

**Proof for channel-like elements.** Given any channel-like element \( Q \in Q \) (translated in space as in Definition 2.1), let \( B_1, B_2 \in B \) (with corresponding radii \( r_1, r_2 \)) denote the inclusions connected by \( Q \) and let \( v_1 := v|_{B_1}, v_2 := v|_{B_2} \in \mathbb{R} \) denote corresponding function values. Assume
for the moment that the channel is parallel, i.e., the radii \( r_1 \) of \( B_1 \) and \( r_2 \) of \( B_2 \) are equal. Then it holds

\[
(3.3) \quad \| \nabla I v \|_{L^2(Q)}^2 \approx \int_Q h(x)^{-2} |v_2 - v_1|^2 \, dx \leq \int_Q \left| \frac{v_2 - v_1}{h(x)} \left( \frac{Q}{r(x)} \right) \right|^2 \, dx.
\]

Since \( r_1 = r_2 \), the function \( h(x) = h(x_1, x_2) = h(x_1) \) solely depends on the first component \( x_1 \) of the space variable \( x \in Q \). Hence,

\[
\sigma(x) := \frac{v_2 - v_1}{h(x)} \left( \frac{Q}{r(x)} \right)
\]

defines a divergence-free vector field in \( Q \) with \( \sigma(x) \cdot n_Q = 0 \) on \( \partial Q \setminus (B_1 \cup B_2) \). We evaluate that

\[
\int_Q \sigma^2 \, dx = \int_{\partial Q} v \sigma \cdot n_Q \, ds
\]

and, hence

\[
\| \sigma \|_{L^2(Q)}^2 = - \| \sigma \|_{L^2(Q)}^2 + 2 \int_{\partial Q} v \sigma \cdot n_Q \, ds
\]

\[
\leq \sup \left\{ - \| \tilde{\sigma} \|_{L^2(Q)}^2 + 2 \int_{\partial Q} v \tilde{\sigma} \cdot n_Q \, ds \mid \tilde{\sigma} \in H(\text{div}, Q) : \begin{array}{l} \text{div} \tilde{\sigma} = 0, \\ (\tilde{\sigma}(x) \cdot n_Q)_{|\partial Q \setminus (B_1 \cup B_2)} = 0 \end{array} \right\}
\]

\[
= \inf \left\{ \| \nabla \tilde{v} \|_{L^2(Q)}^2 \mid \tilde{v} \in H^1(Q) : \tilde{v} = v \text{ on } \partial(B_1 \cup B_2) \right\}
\]

\[
\leq \| \nabla v \|_{L^2(Q)}^2
\]

by duality (see, e.g., [ET76]). The combination of this estimate and (3.3) yields the assertion for the parallel channel \( Q \). The above arguments are easily generalised to the case of a non-parallel channel, i.e., \( r_1 \neq r_2 \), by choosing a suitable parallel channel \( \hat{Q} \subset Q \) and suitable adaptation of \( \sigma \). If one of the inclusions is on the boundary, the result follows from Friedrichs’ (Dirichlet boundary) or Poincaré’s (Neumann boundary) inequality. In the latter case, the right-hand side may depend on \( v \) in some neighbourhood \( \omega_Q \) of \( Q \).

**Proof for triangles.** Again, for elements \( T \in \mathcal{T} \) where \( T \cap \partial Q \) has positive length, the result follows directly from Friedrichs’ or Poincaré’s inequality.

Given any triangle \( T \in \mathcal{T} \), choose \( B_1, B_2 \in \mathcal{B}_{\text{nc}} \) amongst neighbouring inclusions such that corresponding function values \( v_1 := v|_{B_1}, v_2 := |_{B_2} \) have maximal distance. Let \( Q \in \mathcal{Q} \) denote the element that connects the inclusions \( B_1 \) and \( B_2 \). Then it holds

\[
\| \nabla I v \|_{L^2(T)}^2 \leq |v_2 - v_1|^2 \leq \int_Q h(x)^{-2} |v_2 - v_1|^2 \, dx \approx \| \nabla I v \|_{L^2(Q)}^2.
\]

This shows that the energy of \( I v \) on the triangle \( T \) is controlled by the energy of \( I v \) on the neighbouring channel \( Q \) and the assertion follows from the first part of the proof.

The stability of interpolation operator \( I \) implies the following approximation properties.

**Lemma 3.3** (approximation properties of the interpolation). Let \( u \in V \). Then the following estimates hold with constants independent of the (local) mesh size \( h \) and the diameter of the discs in \( \mathcal{B} \).
For all $Q \in Q$,
\begin{equation}
\|h_Q^{-1}(u - Iu)\|_{L^2(Q)} \lesssim \|u\|_{H^1(Q)}.
\end{equation}

For all $T \in T$,
\begin{equation}
\|h_T^{-1}(u - Iu)\|_{L^2(T)} \lesssim \|u\|_{H^1(\omega_T)}
\end{equation}
with the element patch
\begin{equation}
\omega_T := \cup\{Q \in Q : \overline{T} \cap \overline{Q} \neq \emptyset\}.
\end{equation}

For all $E \in E$,
\begin{equation}
\|u - Iu\|_{L^2(E)} \lesssim h_E^{1/2} \|u\|_{H^1(\omega_E)}.
\end{equation}

We emphasize that the mesh size $h_Q$ for $Q \in Q$ is not a constant.

Proof. The localized Friedrichs inequality \cite[Lemma A.1]{Pet12} shows that
\begin{equation}
\|u - Iu\|_{L^2(Q)} \lesssim \|\delta\nabla(u - Iu)\|_{L^2(Q)}
\end{equation}
for any $Q \in Q$ (cf. \cite[Eq. (35)]{Pet12}). It is easily checked that the proof \cite{Pet12} may be modified so that the assertion (3.4) holds on quadrilateral elements. The result (3.5) for triangles $T \in T$ follows immediately from \cite[Eq. (36)]{Pet12}.

To prove (3.7), let $E \in E$ and let $T \in T$ be some triangle with edge $E$. According to \cite{CF00}, the trace inequality for $H^1$ functions yields
\begin{equation}
\|u - Iu\|_{L^2(E)} \lesssim h_E^{1/2} \|\nabla(u - Iu)\|_{L^2(T)} + h_E^{-1/2} \|u - Iu\|_{L^2(T)}.
\end{equation}
The approximation properties of the nodal interpolation operator yield
\begin{equation}
h_T^{-1} \|u - Iu\|_{L^2(T)} \lesssim \|\nabla u\|_{L^2(\omega_T)}.
\end{equation}
The combination of (3.9) and (3.10) is (3.7).}

3.2. Proof of Reliability. We define the residual $Res \in V^*$ for all $v \in V$ by
\begin{equation}
Res(v) := a(e, v) = F(v) - a(u_{NFE}, v).
\end{equation}
Note that the test space of the Galerkin method $V$ employed to obtain $u_{NFE}$ is in the kernel of the residual. Together with some interpolation estimates, the Galerkin orthogonality $S \subset \ker Res$ is key in the derivation of residual estimators.

Since $Iv \in S$ is an admissible test function for any $v \in V$, Galerkin orthogonality and element-wise integration by parts yield
\begin{equation}
a(e, v) = a(e, v - Iv).
\end{equation}
We write the integrals of (3.11) as sum over the elements of $G$ which gives, for $v \in V$,
\begin{equation}
a(e, v - Iv) = \sum_{G \in G} \left\{ \int_G f(v - Iv) \, dx - \int_G \nabla u_{NFE} \cdot \nabla (v - Iv) \, dx \right\}.
\end{equation}
Recall that \((v - Iv)v_{\partial(G_{\text{out}})} = 0\) from \((3.2)\). Then, integration by parts and rearranging terms yields
\[
a(e, v - Iv) = \sum_{G \in \mathcal{G}} \int_{G} r_{G}(v - Iv) \, dx + \sum_{E \in E_{\text{int}}} \int_{E} r_{E}(v - Iv) \, ds.
\]

By use of Cauchy-Schwarz,
\[
a(e, v) \leq \sum_{G \in \mathcal{G}} \|h_{G} r_{G}\|_{L^{2}(G)} \|h_{G}^{-1}(v - Iv)\|_{L^{2}(G)} + \sum_{E \in E_{\text{int}}} \|r_{E}\|_{L^{2}(E)} \|v - Iv\|_{L^{2}(E)}.
\]

With the interpolation estimates of Lemma 3.3 and another application of Cauchy-Schwarz, we arrive at
\[
a(e, v) \leq \|v\|_{H^{1}(\Omega)} \left( \sum_{G \in \mathcal{G}} \|h_{G} r_{G}\|_{L^{2}(G)}^2 + \sum_{E \in E_{\text{int}}} h_{E} \|r_{E}\|_{L^{2}(E)}^2 \right)^{1/2}.
\]

With \(v = e\) we obtain the error estimate
\[
\|\nabla e\|_{L^{2}(\Omega)}^2 \leq \sum_{G \in \mathcal{G}} \|h_{G} r_{G}\|_{L^{2}(G)}^2 + \sum_{E \in E_{\text{int}}} h_{E} \|r_{E}\|_{L^{2}(E)}^2 = \eta^2.
\]

3.3. Proof of Efficiency. The efficiency of \(\eta\) can be derived by a combination of standard arguments, see [Ver96], and the interpolation error estimates of Subsection 3.1.

We denote by \(\psi_{G} \in H^{1}_{0}(G)\) the usual element bubble function on \(G \in \mathcal{G}\) and by \(\psi_{E} \in H^{1}_{0}(\omega_{E})\) the usual edge bubble function with support on the patch \(\omega_{E}\) of edge \(E \in \mathcal{E}\), see [Ver96] for details. The definition of bubble functions on triangular and quadrilateral elements can also be found in [AO00]. Note that an edge bubble function \(\psi_{E}\) is continuous along \(E \in \mathcal{E}\) in both configurations which may occur, i.e., for some \(T_{1}, T_{2} \in \mathcal{T}\) and \(Q \in \mathcal{Q}, E = T_{1} \cap T_{2}\) or \(E = T_{1} \cap Q\).

In any case, the usual estimates for edge bubbles hold; see e.g. [Ver96]. For \(Q \in \mathcal{Q}\), we set \(\psi_{Q} = \psi_{\text{vol}} \circ J_{Q}^{-1}\) the pull-back onto the bubble function of the reference rectangle. Local efficiency is first shown for the volume residual, then for the edge residual.

For some element \(G \in \mathcal{G}\), we set \(v_{G} := \psi_{G} \tilde{r}_{G}\) and deduce
\[
\|h_{G} \tilde{r}_{G}\|_{L^{2}(G)}^2 \leq \int_{G} \tilde{r}_{G}^2 v_{G} \, dx
\]
\[
= \text{Res}(h_{G}^2 v_{G}) - \int_{G} (f - f_{G}) h_{G}^2 v_{G} \, dx
\]
\[
\leq \|\nabla (u - u_{\text{AFEM}})\|_{L^{2}(G)} \|\nabla (h_{G}^2 v_{G})\|_{L^{2}(G)} + \|h_{G}(f - f_{G})\|_{L^{2}(G)} \|h_{G} v_{G}\|_{L^{2}(G)}
\]
\[
\leq \left(\|\nabla e\|_{L^{2}(G)} + \|h_{G}(f - f_{G})\|_{L^{2}(G)}\right) \times \|h_{G} \tilde{r}_{G}\|_{L^{2}(G)}.
\]

Here, we have used the inverse inequality \(\|\nabla (h_{G}^2 v_{G})\|_{L^{2}(G)} \leq \|h_{G} \tilde{r}_{G}\|_{L^{2}(G)}\) on \(G \in \mathcal{G}\) for any \(v \in V(G)\) with a constant independent of the mesh size \(h_{G}\) and \(h_{G} \nabla \psi_{G} \leq C\) with \(C\) depending on anisotropy \(\text{diam}(G)/\sqrt{|G|}\). Such inverse estimates are standard for classical FEM and can be proved with techniques as in [Pet12]. With the split
\[
\|h_{G} r_{G}\|_{L^{2}(G)} \leq \|h_{G} \tilde{r}_{G}\|_{L^{2}(G)} + \|h_{G}(f - f_{G})\|_{L^{2}(G)}
\]
we obtain
\[ \|h_G r_G\|_{L^2(G)} \leq \|\nabla e\|_{L^2(G)} + \text{osc}(f, G). \]

Note that along some edge \(E \in \mathcal{E} \setminus \Gamma_D\) with \(E = G_+ \cap G_-, G_+, G_- \in \mathcal{G}\), the jump \([\nabla u_{\text{NFEM}} \cdot n_E]\) is not constant. Let \(v_E : \omega_E \to \mathbb{R}\) be the piecewise (with regard to \(G_+\) and \(G_-\)) harmonic function with \(v_E|_E = \psi_E[\nabla u_{\text{NFEM}} \cdot n_E]_E\) and \(v_E|_{\partial \omega_E} = 0\). We derive as before
\[
\|[\nabla u_{\text{NFEM}} \cdot n_E]\|_{L^2(E)}^2 \leq \int_{E} \left[\nabla u_{\text{NFEM}} \cdot n_E\right]_E v_E \, ds
\]
\[
= \int_{\omega_E} r_G v_E \, dx - \mathcal{R}es(v_E)
\]
\[
\leq \|r_G\|_{L^2(\omega_E)} \|v_E\|_{L^2(\omega_E)} + \|\nabla e\|_{L^2(\omega_E)} \|\nabla v_E\|_{L^2(\omega_E)}
\]
\[
\leq \left(h_E^{1/2} \|r_G\|_{L^2(\omega_E)} + h_E^{-1/2} \|\nabla e\|_{L^2(\omega_E)}\right)
\]
\[
\times \|[\nabla u_{\text{NFEM}} \cdot n_E]\|_E \|L^2(E).\]

The constant in the trace inequality depends on anisotropy of the element. This, (3.3) and a triangle inequality yields the assertion
\[
\|[\nabla u_{\text{NFEM}} \cdot n_E]\|_{L^2(E)} \leq h_E^{1/2} \|f + \text{div}_{\mathcal{G}} \nabla u_{\text{NFEM}}\|_{L^2(\omega_E)} + h_E^{-1/2} \|\nabla e\|_{L^2(\omega_E)}.\]

Note that edges on the Neumann boundary can be treated in the same way.

## 4. Numerical Examples

This section is concerned with the practical assessment of the Network FEM described in Section 2. In Subsection 4.1 the percolation effect is demonstrated with domains with many densely packed inclusions. When the density of filler particles becomes high enough, connected paths through the domain can emanate which leads to a strong increase of the energy of the solution. We demonstrate that the energy of the solution \(u_{\text{NFEM}}\) depends on the density of particles and on their distance. It is illustrated numerically that the error is basically independent of the inclusion distance and thus of the energy \(\mathcal{E}(u_{\text{NFEM}})\).

In Subsection 4.2 we compare the simulation of inclusions distributed in a structured and in a random way. The striking observation is that for identical volume fraction, i.e., the same number of inclusions, the two settings exhibit completely different properties. While percolation can be seen in the structured case, the energy \(\mathcal{E}(u_{\text{NFEM}})\) stays nearly constant with random particle distributions. Since many methods for multiscale problems like several popular multiscale FEM and classical homogenization assume periodicity of the microscale in the limit, this finding strongly supports the explicit resolution of the actual microscale structure as pursued in the presented Network FEM.

For all computations, model problem (1.3) on the square domain \(\Omega^* := [0, 1]^2\) with equi-sized inclusions is employed. On the left and right boundary, homogeneous Neumann boundary data are prescribed. Dirichlet data is set on the top and bottom boundaries with \(u|_{y=0} = 0\) and \(u|_{y=1} = 1\). Since the problem can be regarded as stochastic due to the randomly distributed particles, a set of realisations is computed and statistics are evaluated afterwards.

In order to obtain an adequate boundary representation with the grid, we mirror the perforated domain \(\Omega\) along all four sides and also along the four corners of \(\Omega^*\). We then apply the algorithm described in Section 2.1. Next, quadrilaterals in \(Q\) which intersect \(\partial \Omega^*\) are identified
and their projections onto $\Omega^*$ are collected in the set of boundary quadrilaterals $Q_{\partial \Omega}$. Likewise, triangles in $T$ whose projection onto $\Omega^*$ does not deteriorate are collected in $T_{\partial \Omega}$. All other new quadrilaterals and all vertices outside of $\Omega^*$ which are not connected to quadrilaterals in $Q_{\partial \Omega}$ are discarded.

Note that there are different approaches for the treatment of the boundaries. One possibility is the insertion of nodes (discs with vanishing radius) onto the boundaries. Another approach is the notion of quasi-discs as described e.g. in [BK01]. A quasi-disc results from an inclusion (close to the boundary) whose projection rays onto the boundary do not intersect any other inclusion. The projection on the boundary then is handled like an inclusion inside the domain.

Remark 4.1. Care has to be exercised to achieve a sufficiently high accuracy for the quadrature on the quadrilateral elements of $Q$ since the transformation map can be highly nonlinear due to inclusions with very small distance. This is particularly critical for the evaluation of integrals of second derivatives as required for the residual error estimator. We employ an adaptive quadrature scheme which subdivides each $T \in Q$ into $O(\log \delta^{-1})$ isotropic elements for which a conventional quadrature rule results in high accuracy. Here, $\delta$ is the distance of the two inclusions which are connected by $T$. Thus, the adapted quadrature does not adversely affect the quasi-optimal complexity of the method.

4.1. Percolation. In this experiment, we assume a set of equi-sized inclusions with increasing density. More specifically, the volume fraction $|B_{\text{inc}}|/|\Omega^*|$ is increased successively up to a value where connected paths of (nearly) touching inclusions are formed. Along these, unhindered decrease of energy is possible and a sudden change of effective conductivity is to be expected. The percolation phenomenon becomes apparent from the energy graphs in Figure 5. In order to facilitate a dense packing, the distribution of inclusions is generated by starting with a structured distribution on a regular lattice and successive removal of random inclusions until the desired density is reached. Depicted in Figure 5 are the energy and error graphs for inclusions with distances $\varepsilon = 10^{-2}, 10^{-4}, 10^{-6}, 10^{-8}$. Additionally, upper and lower energy bounds together with the averaged a posteriori error estimator are plotted. We average with regard to 100 realizations of the random domain with fixed volume fraction. It is expected that the maximal energy increases with smaller distances of inclusions. This is verified numerically in the graphs. The moderate decrease of the a posteriori error estimator can be attributed to the increased approximation quality with more inclusions since these are equivalent to degrees of freedom.

This standard setting can frequently be found in the literature. For instance, it is also examined in [KK07, BK01, Kol07].

4.2. Model validation. This subsection is concerned with the comparison of some structured and some random distribution of inclusions with equal volume fraction up to $VF = 0.5$ for all domains. Our experiments illustrate that a distribution based on a structured setting exhibits fundamentally different behaviour than a random distribution. In particular, the percolation effect which is based on a very dense packing and the formation of some closed path through the domain as discussed in the last section cannot be observed with entirely randomly dispersed inclusions although the same amount of inclusions exists in the domain. In Figure 7, the energy graphs for the structured and the random case are depicted. We also plot the upper bound of the energy subject to the a posteriori error estimator, respectively.
Figure 5. Average energy and a posteriori error estimator for a structured distribution of inclusions with distances $\varepsilon = 10^{-2}, 10^{-4}, 10^{-6}, 10^{-8}$. Upper and lower bounds for the averaged energy due to the error estimator.

This interesting finding questions the assumption of a structured distribution or periodicity in the limit which is the basis for homogenization and many multiscale approaches.

Figure 6. Structured and random test domains with equal volume fraction.
This last section is devoted to some conclusions regarding the presented Network FEM. The method benefits from its relation to network methods as well as from its features inherited from classical FEM. Of the former, the resolution of the small geometrical features of the domain with quasi-optimal complexity is derived. The latter enables the reliable and efficient error control for the discretisation error with some computable a posteriori error estimator. The Network FEM on the one hand is very flexible with regard to the size and shape of the inclusions and may be generalized easily to other settings. On the other hand, it does not suffer from the computational complexity induced by a possibly very fine mesh. It thus succeeds to combine favourable properties of the two related numerical methods.

The proposed method may be understood as a discretisation model for the material behaviour of composite materials. The computational complexity is minimal since it is proportional to the complexity of the data, i.e., the number of inclusions. At the same time, it sustains the critical structural material properties.
